Abstract

Multi-adjoint logic programming represents an extremely flexible attempt for fuzzifying logic programming, where the classical SLD-resolution principle has been extended to cope with imperfect information. In this paper we propose an enhanced tabulation-based query answering procedure, which avoids the generation of useless computations via thresholding techniques.

1 Introduction

Multi-adjoint logic programming [9–11] is an extremely flexible framework which combines fuzzy logic and logic programming. Given a multi-adjoint logic program, queries are evaluated in two separate computational phases. Firstly, an operational phase in which admissible steps (a generalization of the classical modus ponens inference rule) are systematically applied by a backward reasoning procedure, in a similar way to classical resolution steps in pure logic programming; until an expression is obtained in which all atoms have been evaluated. Then, this last expression is interpreted in the underlying lattice during an interpretive phase [6], providing the computed answer for the given query.

In [2] a non-deterministic tabulation goal-oriented proof procedure was introduced for residuated (a particular case of multi-adjoint) logic programs over complete lattices. The underlying idea of tabulation is, essentially, that atoms of selected tabled predicates as well as their answers are stored in a table. When an identical atom is recursively called, the selected atom is not resolved against program clauses; instead, all corresponding answers computed so far are looked up in the table and the associated answer substitutions are applied to the atom. The process is repeated for all subsequent computed answer substitutions corresponding to the atom.

In [7] a fuzzy partial evaluation framework was introduced for specializing multi-adjoint logic programs. Moreover, it was pointed out that if the proposed partial evaluation process is combined with thresholding techniques, the following benefits can be obtained:

- The unfolding tree consumed less computational resources by efficiently pruning unnecessary branches of the tree and, hence, drastically reducing its size.
- Those derivation sequences performed at execution time, need less computation steps to reach computed answers.

In this paper, we show how the essence of thresholding can be also embedded into a tabulation-based query answering procedure and reinforcing the benefits of both methods in a unified framework.

The structure of the paper is as follows. In Section 2 we summarize the main features of

multi-adjoint logic programming. Section 3 adapts to the multi-adjoint logic framework the original tabulation procedure for residuated logic programs of [2]. Inspired by [7], the resulting method is refined by using thresholding techniques in Section 4. Finally, in Section 5 we draw some conclusions and discuss some lines of future work.

2 Multi-Adjoint Logic Programs

This section is a short summary of the main features of multi-adjoint languages. The reader is referred to [9,11] for a complete formulation.

We will consider a language, \( L \), containing propositional variables, constants, several (arbitrary) connectives to increase language expressiveness. In our fuzzy setting, we use implication connectives (\( \rightarrow_1, \rightarrow_2, \ldots, \rightarrow_m \)) together with a number of aggregators, which are only required to be monotonic. They will be used to combine/propagate truth values through the rules. The general definition of aggregation operators subsumes conjunctive operators (denoted by \&_1, \&_2, \ldots, \&_k), disjunctive operators (\( \lor_1, \lor_2, \ldots, \lor_l \)), and average and hybrid operators (usually denoted by \@_1, \@_2, \ldots, \@_n).

Aggregators are useful to describe/specify user preferences: when interpreted as a truth function they may be considered, for instance, as an arithmetic mean or a weighted sum. For example, if an aggregator \@ is interpreted as \[ @ \{x, y, z\} = (3x + 2y + z)/6, \] we are giving the highest preference to the first argument, then to the second, being the third argument the least significant. By definition, the truth function for an \( n \)-ary aggregator \[ @ \{\} : L^n \rightarrow L \] is required to be monotone and fulfill \[ @ \{\} (T, \ldots, T) = T, \] \[ @ \{\} (\bot, \ldots, \bot) = \bot. \]

The language \( L \) will be interpreted on a multi-adjoint lattice, \( \langle L, \preceq, \rightarrow_1, \&_1, \ldots, \&_n, \@_n \rangle \), which is a complete lattice equipped with a collection of adjoint pairs \( \langle \rightarrow_i, \&_i \rangle \), where each \&_i is a conjunctor\(^2\) intended to provide a modus ponens-rule wrt \( \rightarrow_i \). In general, the set of truth values \( L \) may be the carrier of any complete bounded lattice but, for simplicity, in the examples of this work we shall select \( L \) as the set of real numbers in the interval \([0, 1]\).

A rule is a formula \( A \leftarrow_i B \), where \( A \) is an propositional symbol (usually called the head) and \( B \) (which is called the body) is a formula built from propositional symbols \( B_1, \ldots, B_n \) \( (n \geq 0) \), truth values of \( L \) and conjunctions, disjunctions and aggregations. Rules with an empty body are called facts. A goal is a body submitted as a query to the system.

Roughly speaking, a multi-adjoint logic program is a set of pairs \( \langle R; \alpha \rangle \), where \( R \) is a rule and \( \alpha \) is a value of \( L \), which might express the confidence which the user of the system has in the truth of the rule \( R \). Note that the truth degrees in a given program are expected to be assigned by an expert. We will often write “\( R \) with \( \alpha \)” instead of \( \langle R; \alpha \rangle \).

Procedural Semantics

The procedural semantics of the multi–adjoint logic language \( L \) can be thought as an operational phase followed by an interpretive one [6].

In the following, \( C[A] \) denotes a formula where \( A \) is a sub-expression (usually a propositional symbol) which occurs in the (possibly empty) context \( C[\] \), whereas \( C[A/A'] \) means the replacement of \( A \) by \( A' \) in context \( C[\] \). In the following definition, we always consider that \( A \) is the selected propositional symbol in goal \( Q \).

Definition 2.1 (Admissible Steps) Let \( Q \) be a goal, which is considered as a state, and let \( G \) be the set of goals. Given a program \( P \), an admissible computation is formalized as a state transition system, whose transition relation \( \rightarrow_{AS} \subseteq (G \times G) \) is the smallest relation satisfying the following admissible rules:

1. \( Q[A] \rightarrow_{AS} Q[A/v_{k}]; B \) if there is a rule \( \langle A \leftarrow_i B; v \rangle \) in \( P \) and \( B \) is not empty.
2. \( Q[A] \rightarrow_{AS} Q[A/v] \) if there is a fact \( \langle A \leftarrow_i; v \rangle \) in \( P \).

---

\(^2\)An increasing operator satisfying boundary conditions with the top element.
3. $Q[A] \rightarrow_{AS} Q[A/\bot]$ if there is no rule in $P$ whose head is $A$.

Note that the third case is introduced to cope with (possible) unsuccessful admissible derivations. We shall use the symbols $\rightarrow_{AS1}$, $\rightarrow_{AS2}$ and $\rightarrow_{AS3}$ to distinguish between computation steps performed by applying one of the specific admissible rules. Also, the application of a concrete program rule on a step will be annotated as a superscript of the $\rightarrow_{AS}$ symbol, when it was considered relevant.

**Definition 2.2** Let $P$ be a program and let $Q$ be a goal. An admissible derivation is a sequence $Q \rightarrow_{AS} Q'$. When $Q'$ is a formula not containing propositional symbols it is called an admissible computed answer (a.c.a.) for that derivation.

**Example 2.3** Let $P$ be the following program and let $([0,1], \leq)$ be the lattice where $\leq$ is the usual order on real numbers.

$\begin{align*}
R_1 : p &\rightarrow p \quad q \quad r \quad \text{with} \quad 0.8 \\
R_2 : q &\rightarrow p \quad s \quad \text{with} \quad 0.7 \\
R_3 : q &\rightarrow L \quad r \quad \text{with} \quad 0.8 \\
R_4 : r &\rightarrow \quad \text{with} \quad 0.7 \\
R_5 : s &\rightarrow \quad \text{with} \quad 0.9
\end{align*}$

where the labels $P$, $G$ and $L$ stand for Product, Gödel and Lukasiewicz connectives.

In the following admissible derivation for the program $P$ and the goal $\leftarrow p \& q \& r$, we underline the selected expression in each admissible step:

$\begin{align*}
p \& q \& r &\rightarrow_{AS} R_1 \\
(0.8 \& P((0.7 \& p \& q \& r) \& q \& r) \& q \& r) &\rightarrow_{AS} R_2 \\
(0.8 \& P((0.7 \& p \& q \& r) \& q \& r) \& q \& r) &\rightarrow_{AS} R_5 \\
(0.8 \& P((0.7 \& p \& q \& r) \& q \& r) \& q \& r) &\rightarrow_{AS} R_4 \\
(0.8 \& P((0.7 \& p \& q \& r) \& q \& r) \& q \& r) &\rightarrow_{AS} R_1 \\
(0.8 \& P((0.7 \& p \& q \& r) \& q \& r) \& q \& r) &\rightarrow_{AS} R_1
\end{align*}$

The a.c.a.

for this admissible derivation is:

$\begin{align*}
0.8 \& P((0.7 \& p \& q \& r) \& q \& r) \& q \& r
\end{align*}$

If we exploit all propositional symbols of a goal, by applying admissible steps as much as needed during the operational phase, then it becomes a formula with no propositional symbols which can then be directly interpreted in the multi–adjoint lattice $L$. We recall from [6] the formalization of this process in terms of the following definition.

**Definition 2.4 (Interpretive Step)** Let $P$ be a program and $Q$ a goal. We formalize the notion of interpretive computation as a state transition system, whose transition relation $\rightarrow_{IS} (G \times G)$ is defined as the least one satisfying:

$Q[\emptyset(r_1, r_2)] \rightarrow_{IS} Q[\emptyset(r_1, r_2)]$, where $\emptyset$ is the truth function of connective $@$ in the lattice $\langle L, \leq \rangle$ associated to $P$.

**Definition 2.5** Let $P$ be a program and $Q$ an a.c.a., that is, $Q$ is a goal not containing propositional symbols. An interpretive derivation is a sequence $Q \rightarrow_{IS} Q'$. When $Q' = r \in L$, being $\langle L, \leq \rangle$ the lattice associated to $P$, the value $r$ is called a fuzzy computed answer (f.c.a.) for that derivation.

**Example 2.6** We complete the previous derivation of Example 2.3 by executing the necessary interpretive steps to obtain the final fuzzy computed answer, 0.504, with respect to lattice $([0,1], \leq)$.

$\begin{align*}
(0.8 \& P((0.7 \& p \& q \& r) \& q \& r) \& q \& r) &\rightarrow_{IS} (0.8 \& P((0.7 \& p \& q \& r) \& q \& r) \& q \& r)
\end{align*}$

In this section we have just seen a procedural semantics which provides a means to execute multi-adjoint logic programs. However, there exist a more efficient alternative for obtaining fuzzy computed answers for a given query as occurs with the following tabulation-based proof procedure.

3 The Tabulation Proof Procedure

In what follows, we adapt the original tabulation procedure for propositional residuated logic programs described in [2] to the general case of multi-adjoint logic programs [9]. There are two major problems to address: termination and efficiency. On the one hand, the $T_P$ operator is bottom-up but not goal-oriented. Furthermore, the bodies of rules are
all recomputed in every step. On the other hand, the usual implementations of Fuzzy Logic Programming languages (e.g. [12]) are goal-oriented, but inherit the problems of non-termination and recomputation of goals. In order to overcome these problems, the tabulation technique has been proposed in the deductive databases and logic programming communities. Other implementation techniques have been proposed for dealing with uncertainty in logic programming, for instance translation into Disjunctive Stable Models [8], but rely on the properties of specific truth-value domains.

In this section we present a general tabulation procedure for propositional multi-adjoint logic programs. The datatype we will use for the description of the method is that of a forest, that is, a finite set of trees. Each one of these trees has a root labeled with a propositional symbol together with a truth-value from the underlying lattice (called the current value for the tabulated symbol); the rest of the nodes of each of these trees are labeled with an “extended” formula in which some of the propositional symbols have been substituted by its corresponding value. For the description of the adaptation of the tabulation procedure to the framework of multi-adjoint logic programming, we will assume a program \( P \) together with a query \( ?A \). The purpose of the computational procedure is to give (if possible) the greatest truth-value for \( A \) that can be inferred from the information in the program \( P \).

### 3.1 Operations for Tabulation

For the sake of clarity in the presentation, we will introduce the following notation: Given a propositional symbol \( A \), we will denote by \( \mathcal{P}(A) \) the set of rules in \( P \) which have head \( A \). The tabulation procedure requires four basic operations: Create New Tree, New Subgoal, Value Update, and Answer Return. The first operation creates a tree for the first invocation of a given goal. New Subgoal is applied whenever a propositional variable in the body of a rule is found without a corresponding tree in the forest, and resorts to the previous operation. Value update is used to propagate the truth-values of answers to the root of the corresponding tree. Finally, answer return substitutes a propositional variable by the current truth-value in the corresponding tree. We now describe formally the operations:

**Rule 1: Create New Tree.**

Given a propositional symbol \( A \), assume \( \mathcal{P}(A) = \{ (A \leftarrow jB_j; \vartheta_j) \mid j = 1, \ldots, m \} \) and construct the tree below, and append it to the current forest. If the forest did not exist, then generate a singleton list with the tree.

\[
A \leftarrow \vartheta_1 \& B_1 \& \vartheta_2 \& B_2 \& \ldots \& \vartheta_m \& B_m
\]

**Rule 2: New Subgoal.**

Select a non-tabulated propositional symbol \( C \) occurring in a leaf of some tree (this means that there is no tree in the forest with the root node labeled with \( C \) ), then create a new tree as indicated in Rule 1, and append it to the forest.

**Rule 3: Value Update.**

If a tree, rooted at \( C : r \), has a leaf \( B \) with no propositional symbols, and \( B \leftarrow IS^* s \), where \( s \in L \), then update the current value of the propositional symbol \( C \) by the value of \( \text{sup}_L(r,s) \).

Furthermore, once the tabulated truth-value of the tree rooted by \( C \) has been modified, for all the occurrences of \( C \) in a non-leaf node \( B[\ldots, C, \ldots] \) such as the one in the left of the figure below then, update the whole branch substituting the constant \( u \) by \( \text{sup}_L(u,t) \) (where \( t \) is the last tabulated truth-value for \( C \)—i.e., \( \text{sup}_L(r,s) \)—as in the right of the figure.

\[
\begin{array}{c|c}
B[\ldots, C, \ldots] & B[\ldots, C, \ldots] \\
B[\ldots, u, \ldots] & B[\ldots, \text{sup}_L(u,t), \ldots] \\
\vdots & \vdots \\
\end{array}
\]
Rule 4: Answer Return.

Select in any leaf a propositional symbol \( C \) which is tabulated, and assume that its current value is \( r \); then add a new successor node as shown below:

\[
B[\ldots, C, \ldots] \\
B[\ldots, r, \ldots]
\]

Once we have presented the rules to be applied in the procedure, it is worth to recall some facts:

1. The only nodes with several immediate successors are root nodes; the successors correspond to the different rules whose head matches the label of the root node.
2. The leaf of each branch is a conjunction of the truth value of the rule which determined the branch, with an instantiation of the body of the rule.
3. The extension of a tree is done only by Rule 4, which applies only to leaves and extends the branch with one new node.
4. The only rule which changes the values of the roots of the trees in the forest is Rule 3 which, moreover, might update the nodes of existing branches.

3.2 A non-deterministic procedure for tabulation

Now, we can state the general non-deterministic procedure for calculating the answer to a given query by using a tabulation technique in terms of the previous rules.

**Initial step** Create the initial forest with the \textit{create new tree} rule, applied to the query.

**Next steps** Non-deterministically select a propositional symbol and apply one of the rules 2, 3, or 4.

Following the steps in [3] it is not difficult to show both that the order of application of the rules is irrelevant, and that the algorithm terminates under very general hypotheses.

---

**Example 3.1** Consider the following program with mutual recursion and query \( p \):

\[
\begin{align*}
R_1: & \quad p \leftarrow q \quad \text{with} \quad 0.6 \\
R_2: & \quad p \leftarrow r \quad \text{with} \quad 0.5 \\
R_3: & \quad q \leftarrow \quad \text{with} \quad 0.9 \\
R_4: & \quad r \leftarrow \quad \text{with} \quad 0.8 \\
R_5: & \quad r \leftarrow_l p \quad \text{with} \quad 0.9
\end{align*}
\]

Firstly, the initial tree consisting of nodes (i), (ii), (iii) is generated, see Figure 1. Then \textit{New Subgoal} is applied on \( q \), a new tree is generated with nodes (iv) and (v), and its current value is directly updated to 0.9. By using this value, \textit{Answer Return} extends the initial tree with node (vi). Now \textit{Value Update} generates node (vii) and updates the current value of \( p \) to 0.54.

Then, \textit{New Subgoal} is applied on \( r \), and a new tree is generated with nodes (viii), (ix) and (x). \textit{Value Update} increases the current value to 0.8.

By using this value, \textit{Answer Return} extends the initial tree with node (xi). Now \textit{Value Update} generates node (xii). The current value is not updated since its value is greater than the newly computed one.

Finally, \textit{Answer Return} can be applied again on propositional symbol \( p \) on node (x), generating node (xiii). A further application of \textit{Value Update} generates node (xiv) and the
forest is terminated, as no rule performs any modification.

4 Combining Tabulation with Thresholding

In this section we will focus on the concept of thresholding, initially proposed in [7] for safely pruning branches when generating unfolding trees. The original method was firstly introduced inside the core of a fuzzy partial evaluation framework useful not only for specializing fuzzy programs, but also for generating reductants [11].

Fortunately, if queries are evaluated following the tabulation method proposed before, reductants are not required to be included in a program (which obviously would increase both the size and execution time of the final completed program) because their effects are efficiently achieved by the direct use of Rule 3: Value Update, as the reader can easily check.

Anyway, even when reductants are not mandatory in the tabulation framework we have just described, in [7] a refined notion of reductant (called PE-reductant) was supported on the concept of partial evaluation with thresholding, and it is important to recast some useful ideas from there. Partial evaluation (PE) [4] is an automatic program transformation technique aiming at the optimization of a program with respect to parts of its input: hence, it is also known as program specialization. It is expected that the partially evaluated (or residual) program could be executed more efficiently than the original program. This is because the residual program is able to save some computations, at execution time, that were done only once at PE time. To fulfill this goal, PE uses symbolic computation as well as some techniques provided by the field of program transformation [1], specially the so called unfolding transformation (essentially, the replacement of a call by its definition body).

Following this path, the idea is to unfold goals, as much as possible, using the notion of unfolding rule developed in [5,6] for multi-adjoint logic programs, in order to obtain an optimized version of the original program. In [7], the construction of such “unfolding trees” was improved by pruning some useless branches or, more exactly, by avoiding the use (during unfolding) of those program rules whose weights do not surpass a given “threshold” value. For this enhanced definition of unfolding tree we have that:

1. Nodes contain information about an upper bound of the truth degree associated to their associated goal;
2. A set of threshold values is dynamically set to limit the generation of useless nodes.

This last feature provides great chances to reduce the unfolding tree shape, by stopping unfolding of those nodes whose truth degree upper bound component falls down a threshold value $\alpha$.

4.1 Rules for tabulation with thresholding

In what follows, we will see that the general idea of thresholding can be combined with the tabulation technique shown in the previous section, in order to provide more efficient query answering procedures. Specifically, we will discard the previous descriptions of Rule 1: Create New Tree and Rule 2: New Subgoal, and instead of them, we propose new definitions:

Rule 1: Root Expansion.

Given a tree with root $A : r$ in the forest, and a program rule $\langle A \leftarrow lB ; \vartheta \rangle$ not consumed before, such that $\vartheta \not\subseteq r$, append the new child $\vartheta \& lB$ to the root of the tree.

Rule 2: New Subgoal/Tree.

Select a non-tabulated propositional symbol $C$ occurring in a leaf of some tree (this means that there is no tree in the forest with the root node labeled with $C$), then create a new tree with a single node, the root $C : \bot$, and append it to the forest.
There are several remarks to do regarding the new definitions of rules 1 and 2. Firstly, notice that the creation of new trees is now performed in rule 2, instead of rule 1, which justifies its new name. On the other hand, the new rule 1, does not create a new tree by expanding (one level) all the possible children of the root. Instead of it, the Root Expansion rule has a lazy behaviour: each time it is fired, it expands the tree by generating at most one new leaf, if and only if this new leaf might contribute in further steps to reach greater truth degrees than the current one heading the tree. In this sense, the truth degree attached to the root of the tree, acts as a threshold for deciding which program rules can be used for generating new nodes in the tree. Note also that this threshold is dynamically updated by rule Value Update: the more it grows, the less chances for Root Expansion to create new children of the root.

The new non-deterministic procedure for tabulation with thresholding is as follows:

**Initial step** Create an initial tree by using the rule new subgoal/tree on the query.

**Next steps** Non-deterministically select a propositional symbol and apply one of the rules 1, 2, 3, or 4.

In order to show the correctness of the new tabulation procedure, we have just to note that, in the Root Expansion rule, when we generate a leaf \( \vartheta \land \bigwedge \mathcal{B} \) for a root node \( A : \bot \), the value generated by the leaf will always be less than \( \vartheta \), independently of the truth degree eventually computed for the subgoal \( \mathcal{B} \). So, we can safely discard at run-time the use of those program rules (or facts) whose weight \( \vartheta \) falls down the threshold value \( r \). Otherwise, we would generate useless nodes which never would increase the truth degree of the root.

### 4.2 A deterministic procedure for tabulation with thresholding

The main goal of thresholding is to reduce the number and size of trees in the forest. This way, although the order of application of the rules is irrelevant because they generate the same solutions, the refinements introduced by thresholding might produce different forests depending on how and when rules are applied. In this section we provide some heuristics in order to minimize as much as possible the complexity of the generated forest.

To begin with, we assume now that the procedure starts with a forest containing a single tree with root \( A : \bot \), being \( A \) the propositional query we plan to answer.

Obviously, the Root Expansion rule has a crucial role in this sense: the more lazily it is applied, the less chances it has to generate new nodes. So, we assign it the lowest priority in our deterministic procedure. For a similar reason, it is also important to increase the threshold at the root of a tree as fast as possible. In order to do this, we propose:

1. Assign maximum priority to Value Update and Answer Return.

2. When program rules are consumed by Root Expansion in a top-down way, we assume that facts textually appear before rules with body, and program rules are distributed in a descending ordering w.r.t. their weights, whenever possible.

Notice for instance, the distribution of the rules in Example 3.1, which accomplish with the ordering we have just commented. The proposed strategy applied to the example avoids the construction of a number of nodes, see Figure 2, which evidences the benefits of combining tabulation with thresholding.

The answer to the query example with this

\[
\begin{align*}
(i) & \ p : \bot \rightarrow 0.54 \\
(ii) & \ 0.6 \land p \ q \\
(iii) & \ 0.6 \land p \ 0.9 \\
(iv) & \ 0.54 \\
(v) & \ 0.6 \land p \ 0.9 \\
(vi) & \ 0.9 \\
\end{align*}
\]

Figure 2: Example threshold forest for \( p \)
optimized procedure is as follows: the initial tree consisting of nodes (i), (ii) is generated. Then New Subgoal is applied on q, a new tree is generated with nodes (iii) and (iv), and its current value is directly updated to 0.9.

By using this value, Answer Return extends the initial tree with node (v). Now Value Update generates node (vi) and updates the current value of p to 0.54.

Now, Root Expansion prevents using the rule with body r, since its weight is smaller than the currently computed for p. Hence, the forest is terminated.

5 Conclusions and Further Research

In this paper we were concerned with efficient query answering procedures for propositional multi-adjoint logic programs. We have shown that, by using a fuzzy variant of tabulation (specially tailored for the multi-adjoint logic approach) it is possible to avoid the repeated evaluation of redundant goals. Moreover, in the same fuzzy setting, we have also combined tabulation with thresholding, thus safely avoiding other kind of non-redundant, but useless computations.

Nowadays, we are working in a more general version of the proposed method, in order to lift our results to the first order case. For the future, beyond query answering procedures, we also plan to study the role that tabulation combined with thresholding might play in program transformation techniques such as partial evaluation and fold/unfold, in order to efficiently specialize and optimize multi-adjoint logic programs.
